### Abstract

Learning from prior tasks and transferring that experience to improve future performance is critical for building lifelong learning agents. Although results in supervised and reinforcement learning show that transfer may significantly improve the learning performance, most of the literature on transfer is focused on batch learning tasks. In this paper we study the problem of sequential transfer in online learning, notably in the multi-arm bandit framework, where the objective is to minimize the cumulative regret over a sequence of tasks by incrementally transferring knowledge from prior tasks. We introduce a novel bandit algorithm based on a method-of-moments approach for the estimation of the possible tasks and derive regret bounds for it.

## 1 Paper Body

Learning from prior tasks and transferring that experience to improve future performance is a key aspect of intelligence, and is critical for building lifelong learning agents. Recently, multi-task and transfer learning received much attention in the supervised and reinforcement learning (RL) setting with both empirical and theoretical encouraging results (see recent surveys by Pan and Yang, 2010; Lazaric, 2011). Most of these works focused on scenarios where the tasks are batch learning problems, in which a training set is directly provided to the learner. On the other hand, the online learning setting (Cesa-Bianchi and Lugosi, 2006), where the learner is presented with samples in a sequential fashion, has been rarely considered (see Mann and Choe (2012); Taylor (2009) for examples in RL and Sec. E of Azar et al. (2013) for a discussion on related settings). The multi?armed bandit (MAB) (Robbins, 1952) is a simple yet powerful framework formalizing the online learning with partial feedback problem, which encompasses a large number of applications, such as clinical trials, web advertisements and adaptive routing. In this paper we take a step

towards understanding and providing formal bounds on transfer in stochastic MABs. We focus on a sequential transfer scenario where an (online) learner is acting in a series of tasks drawn from a stationary distribution over a finite set of MABs. The learning problem, within each task, can be seen as a standard MAB problem with a fixed number of steps. Prior to learning, the model parameters of each bandit problem are not known to the learner, nor does it know the distribution probability over the bandit problems. Also, we assume that the learner is not provided with the identity of the tasks throughout the learning. To act efficiently in this setting, it is crucial to define a mechanism for transferring knowledge across tasks. In fact, the learner may encounter the same bandit problem over and over throughout the learning, and an efficient algorithm should be able to leverage the knowledge obtained in previous tasks, when it is presented with the same problem again. To address this problem one can transfer the estimates of all the possible models from prior tasks to the current one. Once these models are accurately estimated, we show that an extension of the UCB algorithm (Auer et al., 2002) is able to efficiently exploit this prior knowledge and reduce the regret through tasks (Sec. 3). ? ?

1

The main contributions of this paper are two-fold: (i) we introduce the tUCB algorithm which transfers the model estimates across the tasks and uses this knowledge to achieve a better performance than UCB. We also prove that the new algorithm is guaranteed to perform as well as UCB in early episodes, thus avoiding any negative transfer effect, and then to approach the performance of the ideal case when the models are all known in advance (Sec. 4.4). (ii) To estimate the models we rely on a new variant of method of moments, robust tensor power method (RTP) (Anandkumar et al., 2013, 2012b) and extend it to the multi-task bandit setting1 :we prove that RTP provides a consistent estimate of the means of all arms (for all models) as long as they are pulled at least three times per task and prove sample complexity bounds for it (Sec. 4.2). Finally, we report some preliminary results on synthetic data confirming the theoretical findings (Sec. 5). An extended version of this paper containing proofs and additional comments is available in (Azar et al., 2013).

2

Preliminaries

We consider a stochastic MAB problem defined by a set of arms $A = \{1, \ldots, K\}$, where each arm $i \in A$ is characterized by a distribution $?_i$ and the samples (rewards) observed from each arm are independent and identically distributed. We focus on the setting where there exists a set of models $? = \{? = (?_1, \ldots, ?_K)\}$, $|?| = m$, which contains all the possible bandit problems. We denote the mean of an arm $i$, the best arm, and the best value of a model $? \in ?$ respectively by $?_i(?)$, $i^?(?)$, $??(?)$. We define the arm gap of an arm $i$ for a model $?$ as $i(?) = ??(?) ?_i(?)$, while the model gap for an arm $i$ between two models $?$ and $?0$ is defined as $i(?, ?0) = |?_i(?) ?_i(?0)|$. We also assume that arm rewards are bounded in $[0, 1]$. We consider the sequential transfer setting where at each episode $j$ the learner interacts with a task $??j$,

drawn from a distribution ? over ?, for n steps. The objective is to minimize the (pseudo-)regret RJ over J episodes measured as the difference between the rewards obtained by pulling i? (??j ) and those achieved by the learner: RJ =

J X j=1

Rjn =

J X X

j Ti,n

?j ),

i (?

(1)

j=1 i6=i?

j where Ti,n is the number of pulls to arm i after n steps of episode j. We also introduce some tensor notation. Let X 2 RK be a random realization of the rewards of all arms from a ran? = ?(?), dom model. All the realizations are i.i.d. conditional on a model ?? and E[X—? = ?] where the i-th component of ?(?) 2 RK is [?(?)]i = ?i (?). Given realizations X 1 , X 2 and X 3 , we define the second moment matrix M2 = E[X 1 ? X 2 ] such that [M 2 ]i,j = E[X 1i X 2j ] and the third moment tensor M3 = E[X 1 ? X 2 ? X 3 ] such that [M2 ]i,j,l = E[X 1i X 2j X 3l ]. Since the realizations are conditionally independent, we have that, for every ? 2 ?, E[X 1 ? X 2 —?] = 2 E[X 1 —?] = ?(?) ?P ?(?) and this allows us to rewrite the second and third moments as P? E[X —?] ?2 M2 = ? ?(?)?(?) , M3 = ? ?(?)?(?)?3 , where v ?p = v ? v ? ? ? ? v is the p-th tensor power. Let A be a 3rd order member of the tensor product of the Euclidean space RK (as M3 ), then we define the multilinear map as follows. For a set of three matrices {Vi 2 RK?m }1?i?3 , the (i1 , i2 , i3 ) m?m?m entry is [A(V1 , V2 , V3 )]i1 ,i2 ,i3 := P in the 3-way array representation of A(V1 , V2 , V3 ) 2 R A [V ] [V ] [V ] . We also use different norms: the Euclidean norm j ,j 1 j ,i 2 j ,i 3 j ,i 1 2 3 1 1 2 2 3 3 1?j1 ,j2 ,j3 ?n k ? k; the Frobenius norm k ? kF ; the matrix max-norm kAkmax = maxij —[A]ij —.

3

Multi-arm Bandit with Finite Models

Before considering the transfer problem, we Require: Set of models ?, number of steps n show that a simple variation to UCB allows us for t = 1, . . . , n do to effectively exploit the knowledge of ? and Build ?t = {? : 8i, —?i (?) ? ?i,t — ? "i,t } obtain a significant reduction in the regret. The Select ?t = arg max?2?t ?? (?) mUCB (model-UCB) algorithm in Fig. 1 takes Pull arm It = i? (?t ) Observe sample xIt and update as input a set of models ? including the current ? At each step t, the algoend for (unknown) model ?. rithm computes a subset ?t ? ? containing Figure 1: The mUCB algorithm. only the models whose means ?i (?) are com? of the current model, obtained averaging patible with the current estimates ? ?i,t of the means ?i (?) 1 Notice that estimating the models involves solving a latent variable model estimation problem, for which RTP is the state-of-the-art.

2

Ti,t pulls, and their uncertainty "i,t (see Eq. 2 for an explicit definition of this term). Notice that it is enough that one arm does not satisfy the com-

patibility condition to discard a model ?. Among all the models in ?t , mUCB first selects the model with the largest optimal value and then it pulls its corresponding optimal arm. This choice is coherent with the optimism in the face of uncertainty principle used in UCB-based algorithms, since mUCB always pulls the optimal arm corresponding to the optimistic model compatible with the current estimates ? ?i,t . We show that mUCB incurs a regret which is never worse than UCB and it is often significantly smaller. We denote the set of arms which are optimal for at least a model in a set ?0 as A? (?0 ) = {i 2 A : 9? 2 ?0 : i? (?) = i}. The set of models for which the arms in A0 are optimal is ?(A0 ) = {? 2 ? : 9i 2 A0 : i? (?) = i}. The set of optimistic models for a given model ?? is ?+ = {? 2 ? : ?? (?) ? and their corresponding optimal arms A+ = A? (?+ ). The following theorem bounds the ?? (?)}, expected regret (similar bounds hold in high probability). The lemmas and proofs (using standard tools from the bandit literature) are available in Sec. B of Azar et al. (2013). Theorem 1. If mUCB is run with = 1/n, a set of m models ? such that the ?? 2 ? and q "i,t = log(mn2 / )/(2Ti,t 1 ), (2) where Ti,t

1

E[Rn ] ? K +

X

i2A+

? log mn3 X 2 i (?) 2 log mn3 ? K + ?2 ? , i2A+ min?2? min?2?+,i i (?, ?) i (?, ?) +,i

(3)

where A+ = A? (?+ ) is the set of arms which are optimal for at least one optimistic model ?+ and ?+,i = {? 2 ?+ : i? (?) = i} is the set of optimistic models for which i is the optimal arm. Remark (comparison to UCB). The UCB algorithm incurs a regret ?X ? log n ? log n ? E[Rn (UCB)] ? O ? O K ? ? . i2A mini i (?) i (?)

We see that mUCB displays two major improvements. The regret in Eq. 3 can be written as ?X ? ? ? log n log n E[Rn (mUCB)] ? O ? O —A — + ? ? . i2A+ min?2? mini min?2? i (?, ?) i (?, ?) +,i

+,i

This result suggests that mUCB tends to discard all the models in ?+ from the most optimistic down to the actual model ?? which, with high-probability, is never discarded. As a result, even if other models are still in ?t , the optimal arm of ?? is pulled until the end. This significantly reduces the set of arms which are actually pulled by mUCB and the previous bound only depends on the number of arms in A+ , which is —A+ — ? —A? (?)— ? K. Furthermore, for all arms i, the minimum ? is guaranteed to be larger than the arm gap i (?) ? (see Lem. 4 in Sec. B gap min?2?+,i i (?, ?) of Azar et al. (2013)), thus further improving the performance of mUCB w.r.t. UCB.

4

Online Transfer with Unknown Models

We now consider the case when the set of models is unknown and the regret is cumulated over multiple tasks drawn from ? (Eq. 1). We introduce tUCB (transfer-UCB) which transfers estimates of ?, whose accuracy is improved through episodes using a method-of-moments approach. 4.1

The transfer-UCB Bandit Algorithm

Fig. 2 outlines the structure of our online transfer bandit algorithm tUCB (transfer-UCB). The algorithm uses two sub-algorithms, the bandit algorithm umUCB (uncertain model-UCB), whose objective is to minimize the regret at each episode, and RTP (robust tensor power method) which at each episode j computes an estimate {? ?ji (?)} of the arm means of all the models. The bandit algorithm umUCB in Fig. 3 is an extension of the mUCB algorithm. It first computes a set of models ?jt whose means ? ?i (?) are compatible with the current estimates ? ?i,t . However, unlike the case where the exact models are available, here the models themselves are estimated and the uncertainty "j in their means (provided as input to umUCB) is taken into account in the definition of ?jt . Once 3

Require: number of arms K, number of models m, constant C(?). Initialize estimated models ?1 = {? ?1i (?)}i,? , samples R 2 RJ?K?n for j = 1, 2, . . . , J do Run Rj = umUCB(?j , n) Run ?j+1 = RTP(R, m, K, j, ) end for

the active set is computed, the algorithm computes an upper-confidence bound on the value of each arm i for each model ? and returns the best arm for the most optimistic model. Unlike in mUCB, due to the uncertainty over the model estimates, a model ? might have more than one optimal arm, and an upper-confidence bound on the mean of the arms ? ?i (?) + "j is used together with the upperconfidence bound ? ?i,t + "i,t , which is directly derived from the samples observed so far from arm i. This guarantees that the B-values are always consistent with the samples generated from the actual model ??j . Once umUCB terminates, RTP (Fig. 4) updates the estimates of the model means ?

bj (?) = {? ?ji (?)}i 2 RK using the samples obtained from each arm i. At the beginning of each task umUCB pulls all the arms 3 times, since RTP needs at least 3 samples from each arm to accurately estimate the 2nd and 3rd moments (Anandkumar et al., 2012b). More precisely, RTP uses all the reward samples generated up to episode j to estimate the 2nd and 3rd moments (see Sec. 2) as c2 = j M

l where the vectors ?1l , ?2l , ?3l 2 RK are obtained by dividing the Ti,n samples observed from arm l i in episode l in three batches and taking their average (e.g., [?1l ]i is the average of the first Ti,n /3 2 l c2 and M c3 are consistent estisamples). Since ?1l , ?2l , ?3l are independent estimates of ?(?? ), M mates of the second and third moments M2 and M3 . RTP relies on the fact that the model means ?(?) can be recovered from the spectral decomposition of the symmetric tensor T = M3 (W, W, W ), where W is a whitening matrix for M2 , i.e., M2 (W, W ) = Im?m (see Sec. 2 for the definition of the mapping A(V1 , V2 , V3 )). Anandkumar et al. (2012b) (Thm. 4.3) have shown that under some mild assumption (see later Assumption 1) the model means {?(?)}, can be obtained as ?(?) = (?)Bv(?), where ( (?), v(?)) is a pair of eigenvector/eigenvalue for the tensor T and B := (W T )+ .Thus the RTP algorithm estimates the eigenvectors vb(?) and the eigenvalues b(?), of c3 (W c, W c, W c ).3 Once vb(?) and b(?) are computed, the estimated the m ? m ? m tensor Tb := M j b v (?), where B b is the mean vector ? b (?) is obtained by the inverse transformation ? bj (?) = b(?)Bb T c (for a detailed description of RTP algorithm see Anandkumar et al., 2012b). pseudo inverse of W 2

Notice that 1/3([?1l ]i + [?2l ]i + [?1l ]i ) = ? ?li,n , the empirical mean of arm i at the end of episode l. K?m c c c c ) = Im?m , i.e., W c is the whitening matrix of M c2 . In The matrix W 2 R is such that M2 (W , W 1/2 m?m c c b b b general W is not unique. 4

4.2

Sample Complexity of the Robust Tensor Power Method

umUCB requires as input ”j , i.e., the uncertainty of the model estimates. Therefore we need sample complexity bounds on the accuracy of {? ?i (?)} computed by RTP. The performance of RTP is c2 and M c3 w.r.t. the true

moments. In Thm. 2 we directly affected by the error of the estimates M p prove that, as the number of tasks j grows, this error rapidly decreases with the rate of 1/j. This result provides us with an upper-bound on the error ”j needed for building the confidence intervals in umUCB. The following definition and assumption are required for our result. Definition 1. Let ?M2 = { 1 , 2 , . . . , m } be the set of m largest eigenvalues of the matrix M2 . Define min := min 2?M2 , max := max 2?M2 and max := max? (?). Define the minimum gap between the distinct eigenvalues of M2 as := min i 6= l (— i l —). Assumption 1. The mean vectors {?(?)}? are linear independent and ?(?) ¿ 0 for all ? 2 ?. We now state our main result which is in the form of a high probability bound on the estimation error of mean reward vector of every model ? 2 ?. p 3 Theorem 2. Pick 2 (0, 1). Let C(?) := C3 max + 1/ min + 1/ max ), max / min ( max / where C3 ¿ 0 is a universal constant. Then under Assumption 1 there exist constants C4 ¿ 0 and a permutation ? on ?, such that for all ? 2 ?, we have w.p. 1 q ) C4 m5 K 6 log(K/ ) k?(?) ? bj (?(?))k ? ”j , C(?)K 2.5 m2 log(K/ after j . (5) 2 j min( , )2 3 min

min

min

Remark (computation of C(?)). As illustrated in Fig. 3, umUCB relies on the estimates ? bj (?) and j on their accuracy ” . Although the bound reported in Thm. 2 provides an upper confidence bound on the error of the estimates, it contains terms which are not computable in general (e.g., min ). In practice, C(?) should be considered as a parameter of the algorithm.This is not dissimilar from the parameter usually introduced in the definition of ”i,t in front of the square-root term in UCB. 4.3

Regret Analysis of umUCB

We now analyze the regret of umUCB when an estimated set of models ?j is provided as input. At episode j, for each model ? we define the set of non-dominated arms (i.e., potentially optimal arms) as Aj? (?) = {i 2 A : @i0 , ? ?ji (?) + ”j ¡ ? ?ji0 (?) ”j }. Among the non-dominated arms, when the j actual model is ?? , the set of optimistic arms is Aj+ (?; ??j ) = {i 2 Aj? (?) : ? ?ji (?) + ”j ?? (??j )}. As a result, the set of optimistic models is ?j+ (??j ) = {? 2 ? : Aj+ (?; ??j ) 6= ;}. In some cases, because of the uncertainty in the model estimates, unlike in mUCB, not all the models ? 6= ??j can be discarded, not even at the end of a very long episode. Among the optimistic models, the set of models e j (??j ) = {? 2 ?j (??j ) : 8i 2 Aj (?; ??j ), —? that cannot be discarded is defined as ? ?ji (?) ?i (??j )— ? + + + j ” }. Finally, when we want to apply the previous definitions to a set of models ?0 instead of single S model we have, e.g., Aj? (?0 ; ??j ) = ?2?0 Aj? (?; ??j ).

The proof of the following results are available in Sec. D of Azar et al. (2013), here we only report the number of pulls, and the corresponding regret bound. Corollary 1. If at episode j umUCB is run with ”i,t as in Eq. 2 and ”j as in Eq. 5 with a parameter 0 = /2K, then for any arm i 2 A, i 6= i? (??j ) is pulled Ti,n times such that ? 8 2 log 2mKn2 / ¿ ¿ T ? min i,n ¿ ¿ ?j 2 i (? ) ¿ ¿ Ti,n ? 2 log 2mKn2 / /( ¿ ¿ : Ti,n = 0

,

log 2mKn2 / b i (?; ??j )2 2 min j ?j ?2?i,+ (? )
?j 2 i (? ) ) + 1
+1
if i 2 Aj1 if i 2 Aj2
otherwise

w.p. 1 , where ?ji,+ (??j ) = {? 2 ?j+ (??j ) : i 2 A+ (?; ??j )} is the set of models for which i is among their optimistic non-dominated arms, b i (?; ??j ) = i (?, ??j )/2 "j , Aj1 = Aj+ (?j+ (??j ); ??j ) e j (??j ); ??j ) (i.e., set of arms only proposed by models that can be discarded), and Aj = Aj+ (? + 2 e j (??j ); ??j ) (i.e., set of arms only proposed by models that cannot be discarded). Aj+ (? + 5

The previous corollary states that arms which cannot be optimal for any optimistic model (i.e., the optimistic non-dominated arms) are never pulled by umUCB, which focuses only on arms in i 2 Aj (?j (??j ); ??j ). Among these arms, those that may help to remove a model from the active set +

+

(i.e., i 2 Aj1 ) are potentially pulled less than UCB, while the remaining arms, which are optimal for the models that cannot be discarded (i.e., i 2 Aj2 ), are simply pulled according to a UCB strategy. Similar to mUCB, umUCB first pulls the arms that are more optimistic until either the active set ?jt changes or they are no longer optimistic (because of the evidence from the actual samples). We are now ready to derive the per-episode regret of umUCB. Theorem 3. If umUCB is run for n steps on the set of models ?j estimated by RTP after j episodes with = 1/n, and the actual model is ??j , then its expected regret (w.r.t. the random realization in episode j and conditional on ??j ) is E[Rjn ] ? Remark (negative transfer). The transfer of knowledge introduces a bias in the learning process which is often beneficial. Nonetheless, in many cases transfer may result in a bias towards wrong solutions and a worse learning performance, a phenomenon often referred to as negative transfer. The first interesting aspect of the previous theorem is that umUCB is guaranteed to

never perform worse than UCB itself. This implies that tUCB never suffers from negative transfer, even when the set ?j contains highly uncertain models and might bias umUCB to pull suboptimal arms. Remark (improvement over UCB). In Sec. 3 we showed that mUCB exploits the knowledge of ? to focus on a restricted set of arms which are pulled less than UCB. In umUCB this improvement is not as clear, since the models in ? are not known but are estimated online through episodes. Yet, similar to mUCB, umUCB has the two main sources of potential improvement w.r.t. to UCB. As illustrated by the regret bound in Thm. 3, umUCB focuses on arms in Aj1 [ Aj2 which is potentially a smaller set than A. Furthermore, the number of pulls to arms in Aj1 is smaller than for UCB whenever the estimated model gap b i (?; ??j ) is bigger than i (??j ). Eventually, umUCB reaches the same performance (and improvement over UCB) as mUCB when j is big enough. In fact, the set of optimistic models reduces to the one used in mUCB (i.e., ?j+ (??j ) ? ?+ (??j )) and all the optimistic models have only optimal arms (i.e., for any ? 2 ?+ the set of non-dominated optimistic arms is A+ (?; ??j ) = {i? (?)}), which corresponds to Aj1 ? A? (?+ (??j )) and Aj2 ? {i? (??j )}, which matches the condition of mUCB. For instance, for any model ?, in order to have A? (?) = {i? (?)}, for any arm i 6= i? (?) we need that ? ?ji (?) + ”j ? ? ?ji? (?) (?) ”j . Thus after 2C(?) min min mini

    2
    + 1.

episodes, all the optimistic models have only one optimal arm independently from the actual identity of the model ??j . Although this condition may seem restrictive, in practice umUCB starts improving over UCB much earlier, as illustrated in the numerical simulation in Sec. 5. 4.4

Regret Analysis of tUCB

Given the previous results, we derive the bound on the cumulative regret over J episodes (Eq. 1). Theorem 4. If tUCB is run over J episodes of n steps in which the tasks ??j are drawn from a fixed distribution ? over a set of models ?, then its cumulative regret is RJ ? JK + +

Figure 8: Per-episode regret of tUCB.

This result immediately follows from Thm. 3 and it shows a linear dependency on the number of episodes J. This dependency is the price to pay for not knowing the identity of the current task $\bar{\theta}_j$ . If the task was revealed at the beginning of the task, a bandit algorithm could simply cluster all the samples coming from the same task and incur a much smaller cumulative regret with a logarithmic dependency on episodes and steps, i.e., log(nJ). Nonetheless, as discussed in the previous section, the cumulative regret of tUCB is never worse than for UCB and as the number of tasks increases it approaches the performance of mUCB, which fully exploits the prior knowledge of ?.

## 5
## Numerical Simulations

In this section we report preliminary results of tUCB on synthetic data. The objective is to illustrate and support the previous theoretical findings. We define a set ? of m = 5 MAB problems with K = 7 arms each, whose means $\{\mu_i (\theta)\}_{i,\theta}$ are reported in Fig. 5 (see Sect. F in Azar et al. (2013) for the actual values), where each model has a different color and squares correspond to optimal arms (e.g., arm 2 is optimal for model $\theta_2$ ). This set of models is chosen to be challenging and illustrate some interesting cases useful to understand the

functioning of the algorithm.4 Models ?1 and ?2 only differ in their optimal arms and this makes it difficult to distinguish them. For arm 3 (which is optimal for model ?3 and thus potentially selected by mUCB), all the models share exactly the same mean value. This implies that no model can be discarded by pulling it. Although this might suggest that mUCB gets stuck in pulling arm 3, we showed in Thm. 1 that this is not the case. Models ?1 and ?5 are challenging for UCB since they have small minimum gap. Only 5 out of the 7 arms are actually optimal for a model in ?. Thus, we also report the performance of UCB+ which, under the assumption that ? is known, immediately discards all the arms which are not optimal (i 2 / A? ) and performs UCB on the remaining arms. The model distribution is uniform, i.e., ?(?) = 1/m. Before discussing the transfer results, we compare UCB, UCB+, and mUCB, to illustrate the advantage of the prior knowledge of ? w.r.t. UCB. Fig. 7 reports the per-episode regret of the three 4 Notice that although ? satisfies Assumption 1, the smallest singular value 0.0038, thus making the estimation of the models difficult.

algorithms for episodes of different length n (the performance of tUCB is discussed later). The results are averaged over all the models in ? and over 200 runs each. All the algorithms use the same confidence bound "i,t . The performance of mUCB is significantly better than both UCB, and UCB+, thus showing that mUCB makes an efficient use of the prior of knowledge of ?. Furthermore, in Fig. 6 the horizontal lines correspond to the value of the regret bounds up to the n dependent terms and constants5 for the different models in ? averaged w.r.t. ? for the three algorithms (the actual values for the different models are in the supplementary material). These values show that the improvement observed in practice is accurately predicated by the upper-bounds derived in Thm. 1. We now move to analyze the performance of tUCB. In Fig. 8 we show how the per-episode regret changes through episodes for a transfer problem with J = 5000 tasks of length n = 5000. In tUCB we used "j as in Eq. 5 with C(?) = 2. As discussed in Thm. 3, UCB and mUCB define the boundaries of the performance of tUCB. In fact, at the beginning tUCB selects arms according to a UCB strategy, since no prior information about the models ? is available. On the other hand, as more tasks are observed, tUCB is able to transfer the knowledge acquired through episodes and build an increasingly accurate estimate of the models, thus approaching the behavior of mUCB. This is also confirmed by Fig. 6 where we show how the complexity of tUCB changes through episodes. In both cases (regret and complexity) we see that tUCB does not reach the same performance of mUCB. This is due to the fact that some models have relatively small gaps and thus the number of episodes to have an accurate enough estimate of the models to reach the performance of mUCB is much larger than 5000 (see also the Remarks of Thm. 3). Since the final objective is to achieve a small global regret (Eq. 1), in Fig. 7 we report the cumulative regret averaged over the total number of tasks (J) for different values

of J and n. Again, this graph shows that tUCB outperforms UCB and that it tends to approach the performance of mUCB as J increases, for any value of n.

## 6 Conclusions and Open Questions

In this paper we introduce the transfer problem in the multi?armed bandit framework when a tasks are drawn from a finite set of bandit problems. We first introduced the bandit algorithm mUCB and we showed that it is able to leverage the prior knowledge on the set of bandit problems ? and reduce the regret w.r.t. UCB. When the set of models is unknown we define a method-of-moments variant (RTP) which consistently estimates the means of the models in ? from the samples collected through episodes. This knowledge is then transferred to umUCB which performs no worse than UCB and tends to approach the performance of mUCB. For these algorithms we derive regret bounds, and we show preliminary numerical simulations. To the best of our knowledge, this is the first work studying the problem of transfer in multi-armed bandit. It opens a series of interesting directions, including whether explicit model identification can improve our transfer regret. Optimality of tUCB. At each episode, tUCB transfers the knowledge about ? acquired from previous tasks to achieve a small per-episode regret using umUCB. Although this strategy guarantees that the per-episode regret of tUCB is never worse than UCB, it may not be the optimal strategy in terms of the cumulative regret through episodes. In fact, if J is large, it could be preferable to run a model identification algorithm instead of umUCB in earlier episodes so as to improve the quality of the estimates ? ?i (?). Although such an algorithm would incur a much larger regret in earlier tasks (up to linear), it could approach the performance of mUCB in later episodes much faster than done by tUCB. This trade-off between identification of the models and transfer of knowledge may suggest that different algorithms than tUCB are possible. Unknown model-set size. In some problems the size of model set m is not known to the learner and needs to be estimated. This problem can be addressed by estimating the rank of matrix M2 which equals to m (Kleibergen and Paap, 2006). We also note that one can relax the assumption that ?(?) needs to be positive (see Assumption 1) by using the estimated model size as opposed to m, since M2 depends not on the means of models with ?(?) = 0. P 5 For instance, for UCB we compute i 1/ i .
